EXECUTIVE SUMMARY

This assessment provides guidance for monitoring the environment off the Department of Energy (DOE) Oak Ridge Reservation for the purpose of estimating risks to the nonhuman environment. It is a companion to the screening assessment for human health effects (Hoffman et al. 1990). The approach taken in both assessments was to screen contaminant chemicals into categories that reflect the need for monitoring. In this ecological assessment, the upper screening criterion is a level that indicates acute lethality or other severe effects. The intermediate screening criterion indicates a level of exposure that would be expected to cause low levels of effect in chronic exposures. The lower screening criterion is a "safe" concentration that is based on the intermediate criterion divided by a safety factor. The safety factors are based on consideration of the distribution of sensitivity among species, population and ecosystem processes that can amplify organism-level effects, and the appropriateness of the measures of exposure.

Screening criteria were developed for aquatic organisms, benthic organisms, and piscivorous wildlife and were applied to contaminant concentrations in water, sediment, and fish flesh. The criteria for aquatic and benthic organisms were based on national water quality criteria (NWQC) for protection of aquatic life or equivalent toxicity data. Because there are no sediment quality criteria and no suitable body of sediment toxicity data, the screening criteria for aquatic organisms were compared to estimated concentrations of organic chemicals in interstitial water and concentrations of metals in whole sediment. In addition, bioaccumulation factors were applied to concentrations in fish flesh to estimate water concentrations to which fish had been exposed, and these were compared to the screening criteria. The screening criteria for piscivorous wildlife were developed for this assessment from the best available data.

The exposure data were categorized into ten reaches: Melton Hill Reservoir (MHR), the portion of the Clinch River most influenced by White Oak Creek (WOCC), the Poplar Creek embayment (PCE), the portion of the Clinch River most influenced by Poplar Creek (PCC), Watts Bar Reservoir

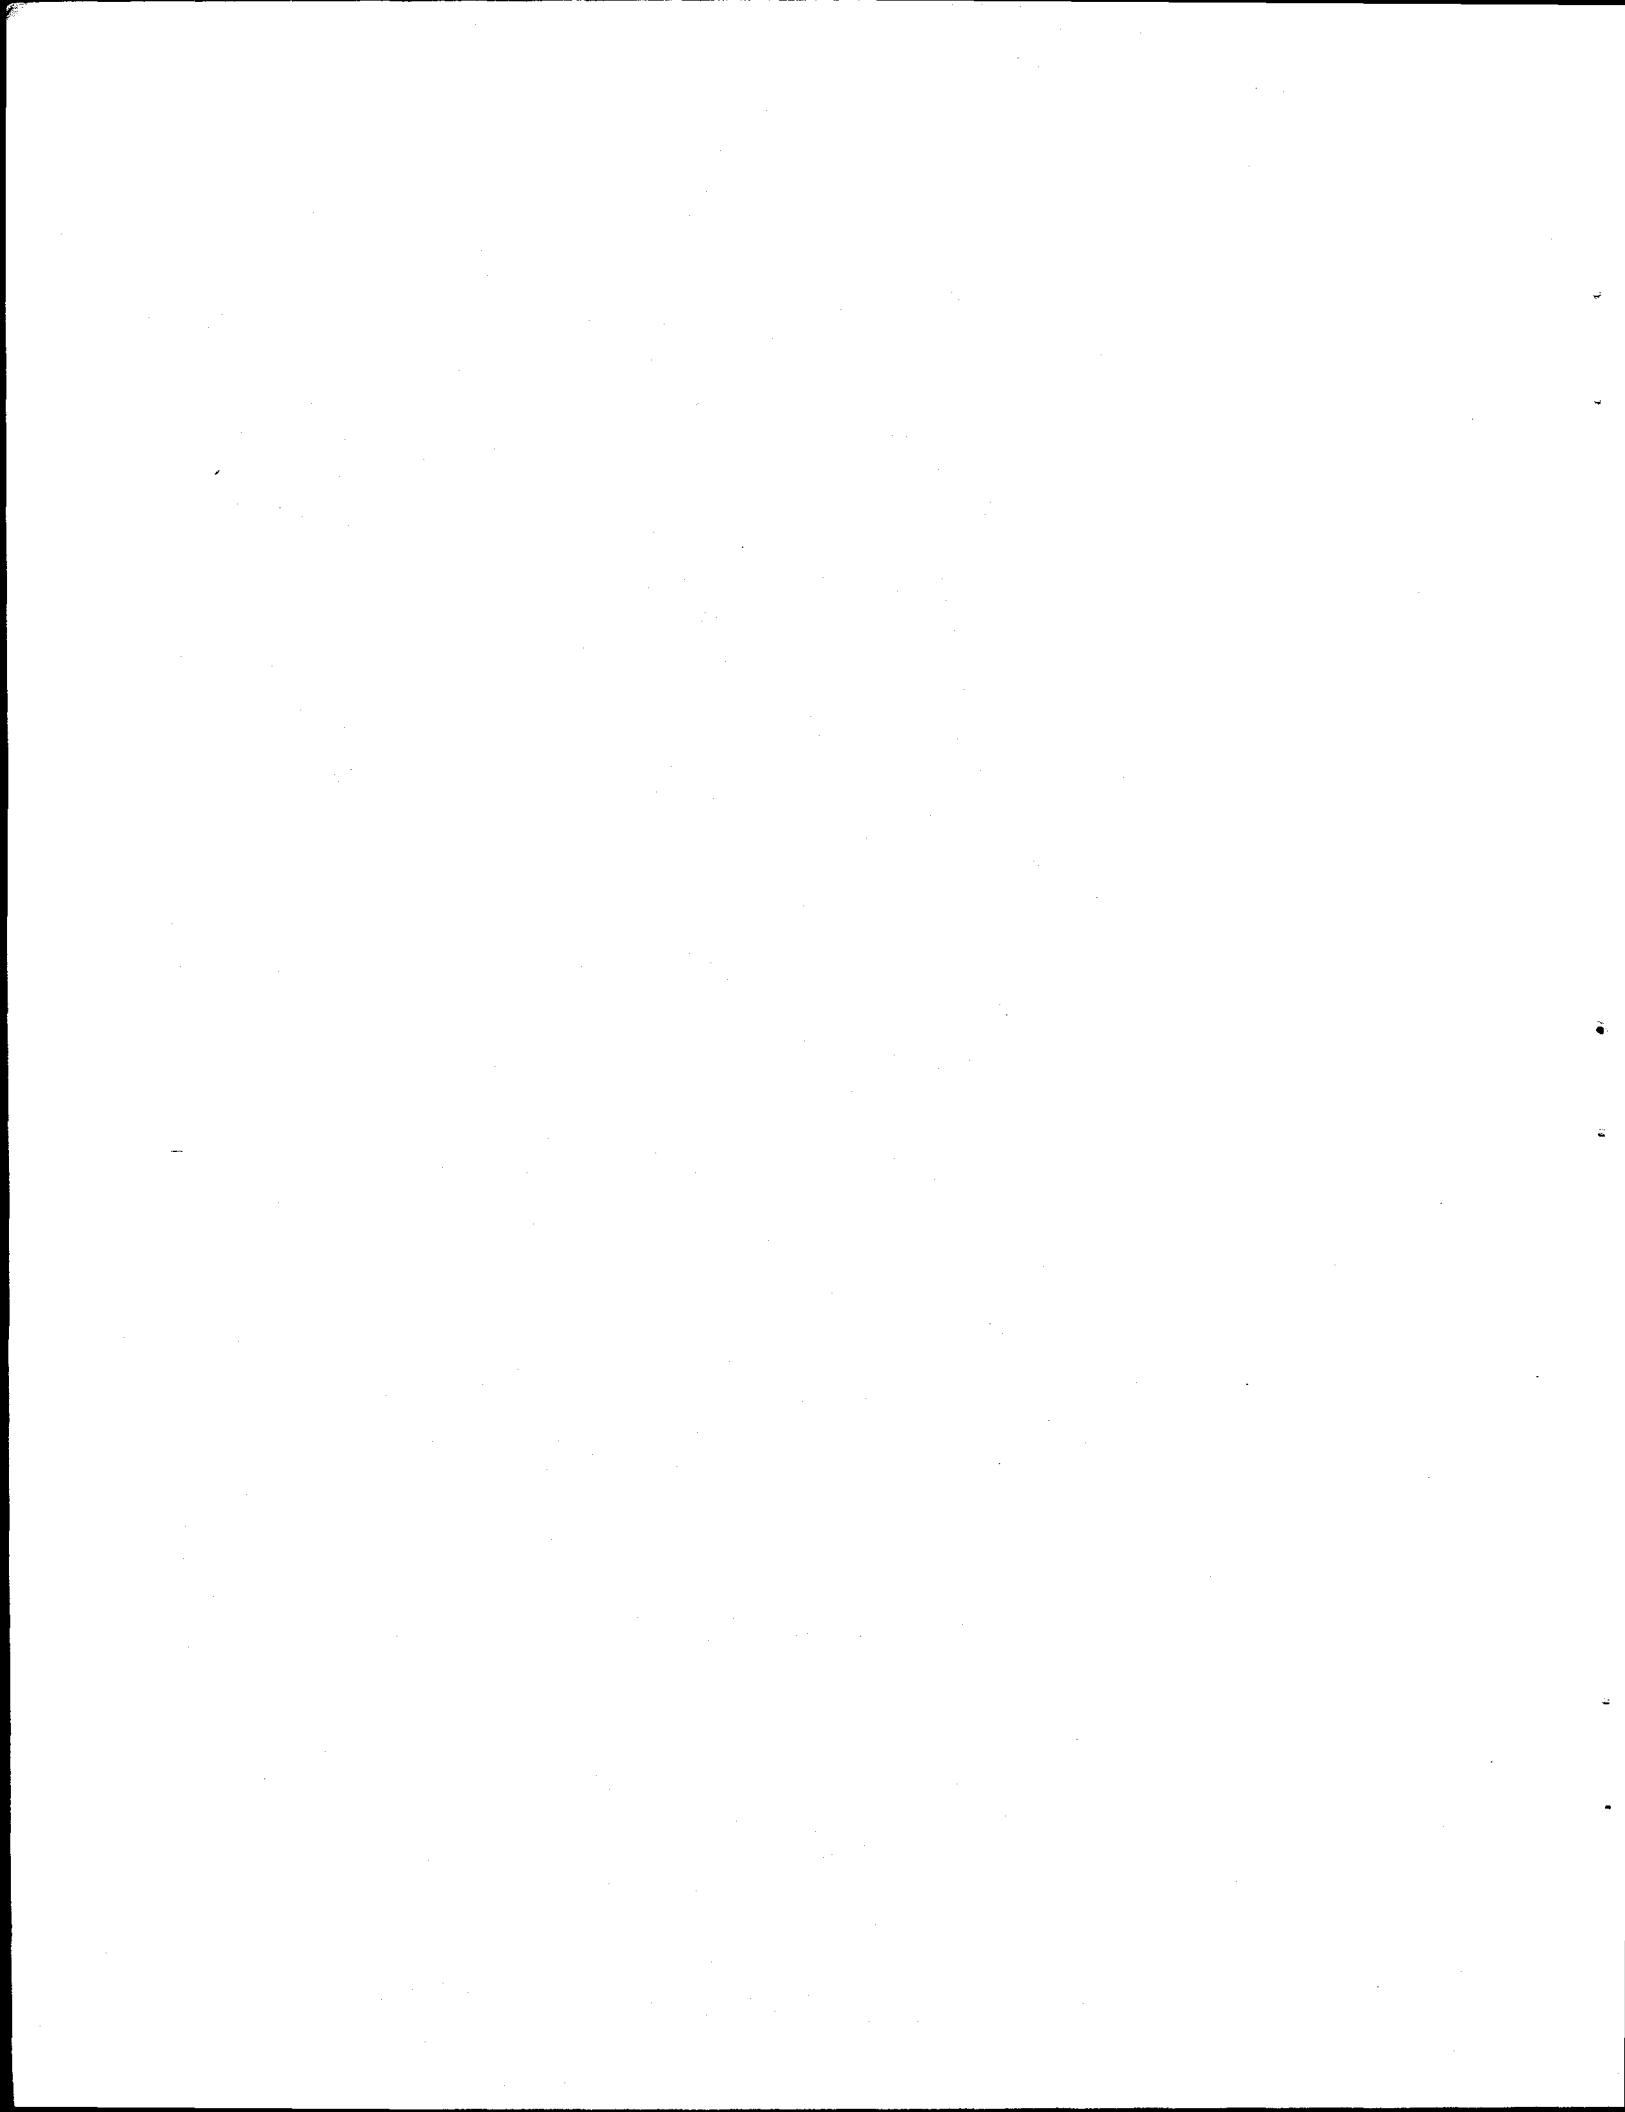

(WBR), Norris Reservoir (NR), Poplar Creek (PC), East Fork Poplar Creek (EF), Tennessee River (TR), and White Oak Lake (WOL). The off-site reaches most influenced by the operations at Oak Ridge facilities are MHR, WOCC, PCE, PCC, and WBR. Negative reference reaches, those that are not influenced by DOE facilities are NR and TR. Positive reference reaches, those that are on-site and heavily influenced by Oak Ridge facilities, are PC, EF, and WOL.

The reported maximum aqueous concentrations of aluminum, arsenic, boron, calcium, cadmium, chromium, copper, cyanide, lead, lithium, mercury, nickel, silver, sodium, uranium, and zinc exceeded upper or intermediate criteria (acute or chronic NWQC or estimated equivalent values) in off-site reaches that are influenced by Oak Ridge operations (MHR, WOCC, PCE, PCC). In addition, the maximum aqueous concentration of pentachlorophenol exceeded the upper criterion and PCB and phthalate ester concentrations exceeded the intermediate criterion in the PCE. Application of bioaccumulation factors to concentrations of arsenic, cadmium, copper, lead, selenium, and silver in fish tissues appears to confirm that exposures to high aqueous concentrations have occurred. However, concentrations of chromium, mercury, nickel, zinc, and PCBs in fish tissues suggest exposure concentrations that are lower than NWQC. Taken together, these results suggest that toxic effects have occurred in these waters. The magnitude and extent of these effects cannot be estimated because the form of the chemicals and their temporal and spatial distributions are undefined. Because the measurements may include biologically unavailable forms of the chemicals, the effects may be much smaller than these results suggest.

The available sediment concentrations for metals other than mercury are uninterpretable. Estimated pore-water concentrations of mercury exceed the intermediate criterion, suggesting that benthic organisms are affected. Intermediate criteria were also exceeded by the maximum estimated pore-water concentrations of Bis(2-ethylhexyl)phthalate in PCE and of phenanthrene in PCE and PCC. The detection limits for many other organic chemicals would result in pore-water concentrations that greatly exceed criteria.

Fish tissue concentrations of mercury are sufficient to cause toxic effects in piscivorous wildlife in all measured reaches including TR, but particularly in PCE and PCC. Selenium in fish from PCC and thallium in fish from MHR may be toxic to wildlife. DDT in the most contaminated fish from MHR and WOCC is sufficient to cause eggshell thinning in piscivorous birds. Mean PCB concentrations in fish are sufficient to cause reproductive failure in mink in all measured reaches but MHR and TR, and mean fish concentrations in those reaches are barely below the observed effects level. These results indicate that piscivorous wildlife along the Clinch River are at risk.

Although this screening assessment was intended primarily to eliminate chemicals from further consideration, it has eliminated relatively few. Metals in general cannot be eliminated because of the inability to interpret sediment concentrations and the high concentrations of several metals in water, sediment, and fish flesh, discussed above. Most of the organic chemicals measured in water were undetected and below screening criteria. However, only chloroform, bromodichloromethane, phenols, and total PCBs were measured in any reach other than the PCE, and they were measured only in WOCC. Therefore, organics in water cannot be eliminated. Most priority organics were measured in sediments from MHR, WOCC, PCE, PCC, and NR. Most were undetected, and some can be eliminated because the estimated pore-water concentration is below the lower criterion, but many are not eliminated. Most priority organics were measured in fish flesh from MHR, WOCC, and PCE, but not from reference reaches. Most were undetected, and many can be eliminated, but it is not possible to determine whether concentrations are elevated or what the sources are because of the absence of reference values. Finally, the occurrence of several chemicals in multiple media at potentially toxic concentrations raises the issue of combined toxic effects that are greater than those induced by any single chemical. Given these results, it is advisable to deemphasize measurement of sources of exposure relative to the measurement of biological indicators of exposure and effects.

1. INTRODUCTION

1.1 BACKGROUND INFORMATION

Operations and waste disposal activities at the Y-12 plant, the Oak Ridge National Laboratory (ORNL), and the Oak Ridge Gaseous Diffusion Plant (ORGDP), located on the U.S. Department of Energy (DOE) Oak Ridge Reservation (ORR) in eastern Tennessee, have introduced a variety of airborne, liquid, and solid wastes into the surrounding environment (Rodgers et al. 1988, 1989). Some of these wastes may affect off-site areas (i.e., areas beyond the ORR boundary) by entering local streams that ultimately drain into the Clinch and Tennessee river systems. Previously reported concentrations of radionuclides, metals, and organic compounds in water, sediment, and biota of the Clinch River and Watts Bar Reservoir suggest the presence of a variety of contaminants of possible concern with regard to the protection of human health and the environment.

The DOE has initiated a comprehensive waste management and environmental restoration effort to achieve the comprehensive remediation of releases of hazardous substances, pollutants, or contaminants from the Oak Ridge Reservation (Jones et al. 1990). This effort has been undertaken in accordance with a draft Federal Facility Agreement (FFA) between the Environmental Protection Agency (EPA) Region IV, the State of Tennessee, and the DOE. The FFA requires that the cleanup of the ORR and environs be conducted in compliance with both the Resource Conservation and Recovery Act of 1976 (RCRA), as amended by the Hazardous and Solid Waste Amendments of 1984 (HWSA), and the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA) of 1980, as amended by the Superfund Amendments and Reauthorization Act of 1986 (SARA).

This preliminary screening of contaminants in the off-site surface water environment downstream of the DOE ORR represents part of the scoping phase of the Clinch River RCRA Facility Investigation (CRRFI), which is a component of the DOE Environmental Restoration Program at Oak Ridge. The primary objectives of the CRRFI are to (1) define the nature and extent of off-site surface-water contamination, (2) quantify the potential risk to human health and to the environment associated with off-site contamination, and (3) identify and preliminarily evaluate potential remediation alternatives.

The purpose of this preliminary screening analysis is to use existing data on off-site contaminant concentrations to identify and prioritize potential contaminants of concern for further evaluation and investigation. The primary objective of this screening analysis is to ensure that CRRFI sampling and analysis efforts focus on those contaminants that may possibly contribute to environmental risk. This analysis is a preliminary scoping exercise based on existing data; it does not constitute a baseline risk assessment, and it is not intended to address issues regarding compliance with regulatory limits.

1.2 ECOLOGICAL RISK ASSESSMENT

Risk assessments, particularly those for hazardous wastes, have largely ignored ecological effects and emphasized human health effects. This bias results in part from anthropocentricity and in part from the mistaken idea that protection of humans will automatically protect the environment. Some chemicals that pose no risk or a negligible risk to humans in drinking or bathing water, such as elevated ammonia, chlorine, and aluminum, or depressed dissolved oxygen, commonly cause mass mortality of aquatic organisms, and many of the national water quality criteria for aquatic life are lower than those for human health. In some cases the greater nonhuman risk is due to routes of exposure that are not credible for humans such as respiring water, drinking from waste sumps, oral cleaning of the pelt or plumage, and root uptake. Other chemicals are inherently more toxic to nonhuman organisms; this is due to modes of action that do not occur in humans (e.g., eggshell thinning by DDT metabolites) or for unknown reasons (e.g., the presence of chlorinated dibenzo-dioxins). There are also modes of action at the ecosystem level, such as eutrophication by nutrients and blockage of light by suspended sediments, that have no analog in human health effects. Finally, even when routes of exposure and modes of action are the same, nonhuman organisms commonly receive a much higher dose than humans. For example, humans eat a few meals a week that have fish as one component, while a bald eagle or otter eats very little other than fish and eats the whole fish, not just the relatively uncontaminated muscle. As a result, the EPA has recently begun to emphasize assessment of ecological effects at waste

sites and has provided guidance for ecological investigations (but not risk assessment) at waste sites (Warren-Hicks et al. 1989).

This screening assessment is not intended to determine what chemicals are causing effects, the nature of effects, or the sources of contamination. Rather, it is intended to guide studies in the off-site surface-water environment by identifying missing information and determining which risks cannot be well defined from existing information. The former task is performed by comparing the existing data concerning off-site contamination with the data set that would be needed to perform a reliable ecological risk assessment. The latter task is performed by applying screening criteria to the available data concerning the concentrations of chemicals in the off-site environment that may be attributable to DOE activities.

2. SCOPE OF THE ASSESSMENT

2.1 SOURCE TERMS

This off-site assessment does not address the individual points of release of chemicals into the environment (e.g., effluent pipes or leaking tanks). Rather, the sources of exposure are the contaminated waters and sediments coming off the Oak Ridge Reservation (ORR). The descriptors of the ongoing off-site contamination are the concentrations of chemicals in waters at the point where they are deemed to leave the site. The primary descriptors of past releases are the concentrations of chemicals in sediments. The source data, which are drawn from various documents and data bases, will be described in a separate document.

2.2 SPATIAL SCOPE OF THE ASSESSMENT

This assessment considers that portion of the environment that receives effluents from DOE's ORR, and that lies beyond the bounds of prior on-site assessments. For aquatic effects, the bounds are the Clinch River from the Solway Bridge over Melton Hill Reservoir to the Watts Bar Dam. This includes the White Oak Creek embayment up to White Oak Dam and the Poplar Creek embayment to the confluence of Poplar Creek and East Fork Poplar Creek.

The streams and rivers are divided into reaches, each of which is given a number, name, and abbreviation (Table 1). The potentially affected reaches are: Melton Hill Reservoir (MHR) (1), which receives leachate from an ash disposal area on McCoy Branch; the White Oak Creek-Clinch (WOCC) (2), which is the portion of the Clinch River that is most influenced by contaminants in White Oak Creek; the Poplar Creek embayment (PCE) (3); the Poplar Creek-Clinch (PCC) (4), which is the portion of the Clinch River most influenced by Poplar Creek; and Watts Bar Reservoir (WBR) (5), which extends from the confluence of the Tennessee River to Watts Bar Dam. There are two negative reference reaches, reaches not influenced by effluents from Oak Ridge operations. They are Norris Reservoir (NR) (10) and the Tennessee River (TR) (18) between Fort Loudon Dam and the confluence of the Clinch River. There are three positive reference reaches, stream reaches that convey emitted chemicals to the

Table 1. Stream and river reaches for the off-site assessment

Reach number	Reach name (description)	Abbreviation
1	Melton Hill Reservoir (from the Solway Bridge to Melton Hill Dam)	MHR
2	White Oak Creek-Clinch (White Oak Creek below White Oak Dam and the Clinch River from Melton Hill Dam to Poplar Creek)	WOCC
3	Poplar Creek embayment (Poplar Creek below the confluence of the East Fork)	PCE
4	Poplar Creek Clinch (the Clinch River from the mouth of Poplar Creek to the confluence with the Tennessee River)	PCC
5	Watts Bar Reservoir (the Tennessee River from the confluence of the Clinch River to Watts Bar Dam)	WBR
10	Norris Reservoir (the Clinch River above Norris Dam)	NR
13	Poplar Creek (Poplar Creek above the confluence of the East Fork)	PC
14	East Fork (the east fork of Poplar Creek)	EF
18	Tennessee River (the reach between Fort Loudon and Tellico Dams and the confluence of the Clinch River)	TR
99	White Oak Lake (White Oak Creek above White Oak Dam)	WOL

off-site reaches. They are Poplar Creek (PC) (13), East Fork Poplar Creek (EF) (14), and White Oak Lake (WOL) (99).

2.3 ASSESSMENT END POINTS

Assessment end points are expressions of the environmental values that are to be protected (Suter 1989). The EPA manual for ecological assessment of hazardous waste sites (Warren-Hicks et al. 1989) indicates that assessment end points should be (1) socially relevant, (2) biologically relevant, (3) operationally definable, (4) measurable or predictable, (5) susceptible to the hazard, and (6) logically related to the decision. For the ecological portion of this assessment, the following end points were chosen as meeting those criteria: (1) a 10% or greater reduction in the abundance or production of the local populations of any fish species, (2) a 10% or greater reduction in the abundance or production of the local populations of any bird species, (3) a 10% or greater reduction in the abundance or production of the local populations of any wild mammal species other than small rodents, (4) a 10% or greater reduction in the production of any local terrestrial plant population (this endpoint is not considered in this assessment), and (5) any toxic effect on individuals of an endangered species sufficient to impair survival or reproduction. It should be noted that effects on species that are not included explicitly in the end points are nonetheless included in the assessment. For example, the only end point species in the aquatic community are fish, but effects on all foodchain species must be included in the assessment of risks to fish.

Except for endangered species, the end points are effects at the population level of biological organization. Unlike human health assessments, ecological risk assessments are not concerned with effects on individual organisms (the exception is endangered species). The fact that hunting, fishing, and harvesting of plants are encouraged implies that individuals are not protected. Higher levels of biological organization (i.e., communities and ecosystems) are not used at present because there is little information on toxic effects at these levels, the toxicity data that are available are highly inconsistent, and effects at higher levels are nearly always less sensitive than those at the

population level. The 10% level of population effects was chosen as approximately the limit of detection of field measurement techniques and is probably below the detection limits of the public (i.e., fishermen would probably not notice a 10% reduction in the abundance of fish).

The end point is defined at the individual level for endangered species because of the greater legal and societal concern for these species. The only federally listed endangered or threatened species that is known to occur in the area being assessed is the bald eagle (Kroodsma 1987). Bald eagles regularly winter along the Clinch River, but not in large numbers, and occasionally appear in the summer. Because they feed primarily on fish, eagles are potentially exposed to contaminants accumulated from water and sediment.

3. METHODS

3.1 SCREENING CRITERIA

A purpose of this assessment is to separate contaminants into three classes: those that require further assessment, those that are clearly unacceptably hazardous, and those that clearly pose no hazard. Therefore, screening criteria must be established to distinguish the three classes of chemicals. The upper criterion is one at which serious effects occur (i.e., an assessment end point is clearly exceeded); the lower criterion is one at which no significant effects occur (i.e., the assessment end points clearly will not be reached). Because of the considerable uncertainty in assessing ecological effects, the lower criteria must be set at very low concentrations to ensure that no chemical that may cause effects is excluded from future monitoring and assessment. For that reason we also use an intermediate screening criterion that corresponds to a concentration that is expected to cause small effects.

In all cases, the upper limit is set at a median acutely lethal concentration or dose (LC_{50} or LD_{50}). Killing half of the members of an exposed population is clearly a serious effect. One can be reasonably certain that unacceptable effects on some population would occur as a result of chronic exposure to a concentration that is acutely lethal in the laboratory, even though there are numerous differences between the circumstances of the test and the field.

The lower criteria are not as consistent as the upper criteria. In setting this criterion, the goal is to approximate a concentration that, with allowance for uncertainties, could not cause a decrease in any population as great as 10%. The intermediate criterion is set at a concentration that has been reported to be a threshold level or a minimal effects level for some effect that could lead to reductions in the productivity of a population (e.g., reduced fecundity, reduced growth, damage to some organ, or low levels of mortality). The methods for deriving screening criteria for each of the contaminated media are discussed below.

3.1.1 Water

The national water quality criteria (NWQC) for protection of freshwater aquatic life provide the basis for the screening criteria for contaminants in water. The acute NWQC are calculated by the EPA as the fifth percentile of the distribution of 48- to 96-hr LC₅₀ values or equivalent effective concentration (EC₅₀) values for each criterion chemical (Stephan et al. 1985). Hence, the acute NWQC correspond to concentrations that would cause 50% mortality in 5% of exposed populations in a few days. This is a reasonable upper screening criterion because this assessment is concerned with continuous exposures, rather than the episodic exposures to which the acute NWQC is applied.

The chronic NWQC are based on the threshold for statistically significant effects in chronic or subchronic toxicity tests, adjusted to estimate the concentration that would exceed that threshold in 5% of species (Stephan et al. 1985). This is the intermediate criterion. The lower screening criterion must be lower than the chronic NWQC for three reasons. First, the chronic NWQC are based on a threshold for statistical significance rather than biological significance. In some chronic tests, because of highly variable results, the statistical threshold corresponds to greater than 50% effect on a response parameter (Stephan and Rogers 1985, Suter et al. 1987). Second, not all important responses are included in the subchronic toxicity tests that are used to calculate many chronic NWQC. In particular, effects on fecundity, which is the most sensitive response parameter on average in fish toxicity tests (Suter et al. 1987), are not included. Third, the chronic NWQC are based on the most statistically sensitive of the measured response parameters in each chronic or subchronic test. Therefore, cumulative effects over the life cycle of fish and invertebrates are not considered. Fourth, the criteria are set at a level that protects "most species most of the time." A lower screening criterion should protect all species nearly all of the time.

Ideally, the lower screening criteria would be generated by calculating a threshold for population-level effects on local fish, invertebrates, and plants for each of the assessed chemicals. However, that would require a large effort, including extraction of the raw data for every chronic toxicity test for fish and invertebrates, fitting

concentration-response models, developing population models for local species, deriving model parameters from the toxicity data, and running the models to estimate threshold effects levels.

Instead, we have calculated lower screening criteria by dividing the chronic NWQC by a correction factor based on prior risk assessments of effects on fish populations. The factor is set at 100, based on two pieces of evidence. First, biologically significant effects on particular response parameters (i.e., 25% mortality or reduction in growth or fecundity) can occur at as little as 1/50 of the statistical threshold concentrations (chronic values) used for the chronic NWQC (Suter et al. 1987). Second, 10% reductions in the relative reproductive potential or the abundance of fish populations are estimated to occur at concentrations between 1/2 and 1/100 of the statistical threshold concentrations used for the chronic NWQC (Barnthouse et al. 1987, Barnthouse et al. 1990). This evidence is not directly applicable to aquatic plants and invertebrates, but we believe that the chosen factor is sufficiently conservative for these organisms also. Aquatic plants do not need a large safety factor because their tests involve all life stages and the end points are based on effects levels. Invertebrates require a safety factor because their chronic test end points are not based on effects levels, but we believe that the factor need not be as large on average as for fish because all life stages are included in common invertebrate chronic tests. It should be emphasized that the lower criterion is not a threshold for effects; it is a concentration that is certain to not cause effects.

NWQC for several metals are functions of water hardness; the criteria are lower for lower hardness levels. We obtained daily hardness measurements from water plants on the reach of the Clinch River covered by this assessment. More than 95% of these are greater than 100 mg/L (the range was 88 to 161 mg/L), so 100 mg/L was used to calculate criteria that are conservative but not extreme.

Some chemicals have no NWQC. In those cases, we use the lowest reported 48- or 96-hr LC₅₀ for the upper screening criterion and the lowest reported threshold for effects in a chronic or subchronic toxicity test of a fish or invertebrate species as the intermediate criteria and to calculate the lower screening criterion. The acute and chronic NWQC would

be as low as these values or lower. If there are only acute lethality data for a chemical, the lowest LC₅₀ or incipient lethal level (ILL) is divided by a correction factor to obtain the intermediate screening criterion. For LC₅₀s the factor is 100, and for ILLs the factor is 20. These are conservative factors in that most measured chronic values would be higher than those estimated from these factors (Suter et al. 1983).

3.1.2 Sediment

The sediment composition data available for this assessment are concentrations in dry sediment. However, effects of a particular dry sediment concentration on sediment-dwelling (benthic) organisms are highly inconsistent. This is because benthic organisms are exposed primarily to chemicals in the aqueous phase of sediments (Adams et al. 1985, OWRS 1989). Therefore, it is necessary to estimate the concentration in pore (interstitial) water. Pore-water concentrations of neutral (non-ionic) organic chemicals can be calculated by assuming equilibrium partitioning between the pore water and the organic matter fraction of the sediment (OWRS 1989). The partitioning coefficient (K_p) is the product of the organic matter/water partitioning coefficient (K_{oc}) and the fractional organic matter content of the sediment (f_{oc}). Because sediment-dwelling organisms are approximately as sensitive to chemicals in water as the population of species used to derive the NWQC (OWRS 1989), the same screening criteria can be used as for water but corrected for partitioning. The formula is:

$$C_s = K_p C_w , \text{ or}$$

$$C_s = K_{oc} f_{oc} C_w ,$$

where C_s and C_w are the screening criteria for sediment and water, respectively. K_{oc} is seldom available, but it is quite accurately approximated by the octanol/water partitioning coefficient (K_{ow}) (DiToro 1985).

Concentrations of ionic organic chemicals and inorganic chemicals in pore water could, in theory, also be calculated from an equilibrium partitioning model. However, these chemicals are sorbed to multiple sediment components so they would require several-phase partitioning

models with a partitioning coefficient and concentration in sediment for each phase, information that is not available. We assume that ionic organics behave like neutral organics, only partitioning between water and sediment organic matter. This is a conservative assumption because partitioning to other phases would lower the aqueous concentration, thereby lowering the toxicity of a given whole-sediment concentration. For metals in sediments, we use the even more conservative assumption that all of the metal is available.

Another approach is to derive site-specific sediment-water partitioning coefficients. Blaylock et al. (in review) have proposed a sediment-water partitioning coefficient for mercury in Watts Bar Reservoir of 10^5 . This value is derived from concentrations of mercury in suspended particulate matter and filtered water from Tennessee River Mile 545. It is probably a reasonable estimate of the mercury K_p , although suspended solids differ from bed sediments, and K_p varies with solids concentration (OWRS 1989) and redox potential.

Besides the risks to benthic organisms, it is necessary to consider risks to water-column species from chemicals associated with resuspended sediments. We believe that the screening criteria for benthic organisms are sufficiently conservative for this purpose. That belief is based on the following arguments: (1) the screening criteria are based on an assumption of chronic exposure, but exposures to suspended sediments would be acute; (2) dilution would rapidly decrease the aqueous concentration outside the plume and also within the plume once the particulate concentration dropped sufficiently to prevent attainment of equilibrium; and (3) the biological component of the sediment criteria is applicable because it is based primarily on water-column species.

3.1.3 Tissue Concentrations as Indicators of Effects on Fish

Tissue concentrations can be used in two ways to derive screening criteria. First, for a few chemicals there are data on the tissue concentrations at which effects occurred. When they are available, these data will be used to derive criteria. When they are not available, it is necessary to use conventional aquatic toxicity data that are expressed as aqueous concentrations. In that case, bioaccumulation factors (BAFs) are

used to estimate the average water concentrations to which fish have been exposed (fish tissue concentration/BAF = water concentration). When available, field-derived BAFs are used. Otherwise, laboratory-derived BAFs, or BAFs derived from models of laboratory data [i.e., quantitative structure-activity relationships (QSARs)], are used. The laboratory-derived factors are likely to overestimate the water concentrations for those chemicals that are accumulated through food chains, but these overestimates will tend to highlight those chemicals. The same upper, intermediate, and lower criteria that are used for water concentrations are then applied to the calculated water concentration to serve as a screen for the fish tissue concentrations.

3.1.4 Tissue Concentrations and Aquatic Food Chains

The contamination in fish and aquatic invertebrate tissues represents a route of exposure for piscivorous mammals, birds, reptiles, and fish. As with the other analyses, the upper screening criteria for piscivores are based on acute lethality. Usually these are acute median lethal doses (LD_{50}) but lethal concentrations in food (LC_{50} or LC_x) are preferred. Doses (mg of chemical/kg of animal) must be converted to concentrations in food by dividing by consumption (kg of food/kg of animal). Local piscivorous birds range from kingfishers to great blue herons, ospreys, and bald eagles. The highest dose would be obtained by the smallest bird (because of higher metabolism), and a predatory bird the size of a kingfisher consumes food equivalent to approximately 8% of its body weight per day (Kenaga 1973). The principal piscivorous mammal in the area is the mink. We assume that mink consume food equal to 5% of their body weight per day. The 8% figure is used to calculate the screening criteria because it is more conservative, but we consider effects on mink in the discussion of results. For the conversion of acute dose to concentration in diet, we assume that one day's consumption is equivalent to an acute dose.

The lower screening criteria for aquatic foodchain exposures are quite diverse because test data for chronic oral exposures to birds and mammals are quite diverse. When data are available concerning the dietary toxicity of a chemical to wildlife, the lowest test concentration that

reflects a potential effect on populations is used. If there are no wildlife data, any available data on domestic animals other than ruminants are used. In many cases, there are no useful wildlife or domestic animal data, and the same laboratory rodent data that are used for human health effects are used in the screening criteria. Toxicity data for ruminants are the least desirable because their peculiar digestive systems make their responses unrepresentative of nonruminants. Data from dietary toxicity tests are preferred to chronic oral dosing tests. The effects include systemic toxicity, reduced reproduction, severe histological damage, and terata. We do not assess cancer induction in nonhuman species because the higher wildlife exposure is not sufficient to overcome the extremely low frequencies of cancer induction (i.e., 10^{-6}) used for the human health screening analysis. Although tumors have frequently been found in fish in other studies, effects of cancer on fish population size or productivity have not been demonstrated.

Unlike the screening criteria that are based on NWQC, these criteria do not reflect the diversity of organisms that are exposed by this route. If chronic sublethal effects data are available for either mammals or birds but not both, a correction factor of 10 for differences in sensitivity is applied. This factor is based on limited studies that indicate that birds and mammals can differ in sensitivity by more than an order of magnitude and either can be more sensitive (Sigal and Suter 1989). If there are data for both birds and mammals, but fewer than five species with fewer than two birds, a factor-of-5 correction for differences in sensitivity is assumed. If there are data for five or more species including at least two avian species, we assume that the variance in sensitivity of the test species approximates the variance in all avian and mammalian species and apply no factor for differences among species. If the most sensitive test end point is death or another severe effect (e.g., reproductive failure), a factor of 5 is applied to estimate the threshold for effects on individuals that could result in population reductions (Tucker and Lietzke 1979). These factors are not applied to the upper criterion, which is intended to be a concentration at which effects are certain.

Because the studies of chemical concentrations in fish that were conducted in the Oak Ridge area were designed for human health risk assessments, the reported concentrations refer to the "edible portion." Piscivores typically consume the entire fish, and the organs and bones contain higher levels than the muscles of nearly all chemical contaminants. Metals concentrations in whole fish (minus gut contents) tend to be approximately 1.5 to 2 times as high as in fillets or carcasses (Lemly and Smith n.d., Brumbaugh and Kane 1985). Hydrophobic organic chemicals like PCBs occur in whole fish at 2 to 3 times the concentration in fillets. Therefore, we apply a factor of 2 to metal concentrations in fish and a factor of 3 to organic chemical concentrations in fish when calculating lower and intermediate criteria.

Another source of error is the moisture content of the food. The concentrations reported from dietary toxicity data are usually based on the weight of the food as consumed by the animal (i.e., fresh weight), but may be reported as dry weight. In addition, the water content of foods is variable and is often unreported in dietary toxicity studies. The concentrations in fish provided for this assessment are fresh weight. We assume, unless the source indicates otherwise, that the toxic concentrations are also fresh weight and that the water content of the diet and of fish fillets is approximately equal. This assumption could result in an error of approximately a factor of 5 in the results.

In addition to the uncertainties discussed above, this analysis of risks to piscivorous birds and mammals does not include other animals that feed on aquatic organisms. Reptiles and amphibians feed on aquatic invertebrates and fish but hardly any data exist on dietary toxicity for these taxa. Raccoons and diving ducks consume aquatic invertebrates, but tissue analyses are not available for invertebrates in the waters being assessed. We assume that, because they feed from a variety of sources other than aquatic invertebrates, these populations will be protected by the criteria for piscivores. Dabbling ducks consume aquatic macrophytes, but there are not enough data concerning contamination of these sources to perform an assessment and too few macrophytes in the Clinch River to serve as a significant source of exposure. Dietary exposure of predatory fish to contaminated fish and invertebrates is not a significant route of

exposure except for the most bioaccumulative chemicals. These are discussed along with the results on exposure to water.

3.2 DATA FOR INDIVIDUAL CRITERIA

The values for NWQC are taken from EPA (1986a). Bioaccumulation factors and K_{ow} values are from Barnthouse et al. (1988). Other sources of data used to derive criteria for individual chemicals are discussed below.

3.2.1 Metals and Metaloids in Water

Aluminum. The proposed acute and chronic NWQC for aluminum for circumneutral waters are 750 and 87 $\mu\text{g}/\text{L}$, respectively (EPA 1988b). These are used as the upper and intermediate criteria; applying the factor of 100 yields a lower screening criterion for these waters of 0.87 $\mu\text{g}/\text{L}$.

Mercury. Because the chronic NWQC for mercury is based on bioaccumulation and effects on humans, the intermediate criterion for concentrations in water must be estimated from the lowest freshwater "chronic value," which is 0.26 $\mu\text{g}/\text{L}$ for inorganic divalent mercury and 0.07 $\mu\text{g}/\text{L}$ for methylmercury (EPA 1986a, Snarski and Olson 1982). Applying the factor of 100 for population thresholds yields lower criteria of 0.0026 $\mu\text{g}/\text{L}$ and 0.0007 $\mu\text{g}/\text{L}$. Inorganic mercury accumulates to 1.36 mg/kg in whole fathead minnows at the 0.26- $\mu\text{g}/\text{L}$ exposure concentration (Snarski and Olson 1982). Brook trout exposed to methylmercury experienced toxic effects at carcass concentrations of 1.6-4.4 mg/kg and whole-body concentrations of 3.4-9.4 mg/kg (McKim et al. 1976).

Phosphorus. The form of phosphorus in some measurements is not indicated. Although the most common forms are expected to be organic phosphorus and phosphates, for the sake of screening we must assume that it is elemental phosphorus, which is highly toxic. A recommended chronic criterion for elemental phosphorus of 0.04 $\mu\text{g}/\text{L}$ (Bentley et al. 1978) is used as the intermediate criterion. The upper criterion is set at 6 $\mu\text{g}/\text{L}$ based on the lowest reported LC₅₀ (Bentley et al. 1978, EPA 1986a).

Phosphate phosphorous. Phosphate in excess of 25 $\mu\text{g}/\text{L}$ can cause nuisance algal blooms (EPA 1976).

Vanadium. The threshold for chronic toxicity of vanadium to flagfish was 0.08 mg/L (Holdway and Sprague 1979). This value serves as the estimate of a chronic NWQC.

Other metals. The estimate of the chronic NWQC for barium, calcium, cobalt, magnesium, manganese, potassium, sodium, strontium, and tin is the threshold for reproductive effects on *Daphnia magna* reported by Biesinger and Christensen (1972). The estimated chronic NWQC for boron, lithium, molybdenum, thorium, titanium, and uranium is the lowest ILL or LC₅₀ from Cushman et al. (1977) or AQUIRE (EPA 1988a) divided by the appropriate correction factor.

3.2.2 Organics in Water

Benzene. There is no freshwater chronic NWQC for benzene, but application of the saltwater acute/chronic ratio to the freshwater final acute value (EPA 1980s) yields an estimated chronic NWQC (intermediate criterion) of 0.727 mg/L.

Benzidine. There are no chronic aquatic toxicity data for benzidine. Applying the acute/chronic ratio of 100 to the acute NWQC (2.5 mg/L) yields an intermediate criterion of 0.025 mg/L.

Chlorinated naphthalenes. There are no suitable freshwater chronic toxicity data, but application of the saltwater acute/chronic ratio to the freshwater final acute value (EPA 1980t) yields an intermediate criterion of 0.444 mg/L.

Chloroalkyl ethers. The only chronic aquatic toxicity test for this class of chemicals gave a no-observed-effect concentration (NOEC) of >19 mg/L (EPA 1980u). This value is used as a conservative intermediate criterion.

Chloroethane. No aquatic toxicity data were found for chloroethane. Because the toxicity of hydrocarbons generally increases with the number of chlorine substitutions, the value for dichloroethane, 20 mg/L (EPA 1986a), is used as a conservative value for the monochloro form.

Dichloroethene. The only chronic aquatic toxicity test for this chemical gave a NOEC of >2.8 mg/L (EPA 1980v). This value is used as a conservative intermediate criterion.

Ethylbenzene. The only chronic aquatic toxicity test for this class of chemicals gave a NOEC of >0.44 mg/L (EPA 1980w). This value is used as a conservative intermediate criterion.

Fluoranthene. In the absence of NWQC, the upper criterion for fluoranthene is the lowest LC₅₀ for freshwater organisms (4 mg/L) and the intermediate criterion is the lowest chronic value for aquatic life (0.016 mg/L) (EPA 1986a).

Fluorene. There are no chronic aquatic toxicity data for fluorene. The lowest freshwater LC₅₀ is 600 µg/L (Eisler 1987b) which, divided by the generic acute/chronic ratio of 100, yields an intermediate criterion of 6 µg/L. The BAF of 600 is the mean of the range given by Eisler (1987b).

Halomethanes. There is no freshwater chronic NWQC for halomethanes, but application of the saltwater acute/chronic ratio to the freshwater final acute value (EPA 1980x) yields an intermediate criterion of 4 mg/L.

Hexachlorobenzene. This chemical is too sparingly soluble to induce acute lethality and has not been tested for chronic toxicity (Call et al. 1983). A LC₅₀ for pentachlorobenzene (the most similar chemical for which there are doxicity data) of 0.25 mg/L divided by the acute chronic ratio for 1,2,4,5-tetrachlorobenzene (the most similar chemical for which there are chronic toxicity data) (EPA 1980i) yields an intermediate criterion of 0.038 mg/L.

Isophorone. There is no freshwater chronic NWQC for isophorone, but chronic values for fathead minnows and *Daphnia magna* are 14 and 15 mg/L, respectively (Cairns and Nebeker 1982). Hence we use 14 mg/L as the intermediate criterion.

Nitrobenzene. The only chronic aquatic toxicity test for this chemical gave a NOEC of >32 mg/L (EPA 1980k). This value is used as a conservative intermediate criterion.

Nitrosamines. There are no chronic aquatic toxicity data for nitrosamines. Applying the acute/chronic ratio of 100 to the lowest LC₅₀ [5.85 mg/L (EPA 1980l)], yields an intermediate criterion of 0.058 mg/L.

PCBs. The chronic NWQC for protection of aquatic life is based on effects on mink, so it is not applicable to fish and aquatic invertebrates. The lowest freshwater chronic value of 0.2 µg/L (EPA 1980d) serves as the intermediate criterion.

Phenanthrene. In the absence of chronic toxicity data, the lowest LC₅₀ [370 µg/L (Eisler 1987b)] was divided by the generic acute/chronic ratio to obtain an intermediate criterion of 3.7 µg/L. The BAF of 325 is the value for *Daphnia magna* from Eisler (1987b).

Pyrene. The BAF for pyrene of 69 is the value for rainbow trout in Eisler (1987b).

Toluene. There is no freshwater chronic NWQC for toluene, but application of the mean saltwater acute/chronic ratio to the freshwater final acute value (EPA 1980y) yields an estimated chronic NWQC of 0.23 mg/L.

3.2.3 Metals and Metaloids in Fish

Antimony. Antimony causes liver damage in rabbits at 5.5 mg/kg in diet (NRC 1980). Application of a factor of 10 for variance in sensitivity and 2 for the whole-fish conversion yields a lower criterion for piscivores of 0.3 mg/kg.

Arsenic. The toxicity and bioaccumulation of arsenic are highly dependent on the form. The most toxic and bioaccumulative form is inorganic trivalent arsenic (arsenite salts). Median lethal dietary concentrations for wildlife range from 99.8 mg/kg in cowbirds to >5000 mg/kg in mallards depending on the arsenical species as well as the biological test species (NRC 1977, NIOSH 1988), so the upper criterion for piscivores is set at an approximate median of 1000 mg/kg. Reported sublethal effects of inorganic arsenic largely fall in this interval, but there is very little information on sublethal effects on birds. The most sensitive reported dietary effect in mammals or birds is the NOEC for growth of rats of 31 mg/kg (NRC 1977, EPA 1985). Applying a factor of 5 for species sensitivities and 2 for whole fish results in a lower criterion for effects on piscivores of 3 mg/kg.

Beryllium. Beryllium is a serious respiratory toxin and carcinogen, but has not been noted to cause dietary toxicity. The oral LD₅₀ in rats is 9.7 mg/kg (EPA 1980r), giving a dietary upper screening criterion of 120 mg/kg. Weight loss occurred in rats fed a diet containing 500 mg/kg beryllium (EPA 1987). Applying a factor of 10 for variance in sensitivity

and 2 for the whole-fish conversion yields a lower screening criterion for piscivores of 25 mg/kg.

Cadmium. The National Research Council (1980) set the maximum tolerable level for cadmium in animal feed at 0.5 mg/kg based on observed toxic effects in mammals on 1-mg/kg diets. This appears to be sufficient to protect birds because the lowest-reported-effects level in birds is 4 mg/kg (Heinz et al. 1983). The factor of 2 for whole-fish concentrations gives a lower screening criterion for piscivores of 0.25 mg/kg.

Chromium. Chromium is most toxic to aquatic organisms in the hexavalent form. That is the form used in cooling towers, and it is the form that we assume for the aqueous chromium concentrations used in this assessment. However, it is likely that much of the chromium has been reduced to the trivalent form in fish tissues. There are little appropriate data for estimating chromium effects on wildlife, but young black ducks experienced reduced growth and survival at 10 mg/kg chromium (III) in diet (Eisler 1986). We apply a factor of 5 for variance in sensitivity and 2 for whole fish to derive a lower screening criterion for piscivores of 1 mg/kg.

Copper. Copper is a well-regulated essential nutrient that is seldom toxic in terrestrial vertebrates. The National Research Council (1980) set the maximum tolerable level for the most sensitive mammal (sheep) at 25 mg/kg, for nonruminant mammals at 100 to 800 mg/kg, and for chickens and turkeys at 300 mg/kg. Applying a factor of 2 to the lowest nonruminant level yields a lower screening criterion for piscivores of 50 mg/kg.

Lead. The National Research Council (1980) recommended that lead in livestock food be limited to 30 mg/kg, which appears to be protective of other species (EPA 1984a, Eisler 1988). We apply a factor of 2 for whole fish to derive a lower screening criterion for piscivores of 15 mg/kg.

Mercury. A U.S. Fish and Wildlife Service report has recommended that mercury in wildlife food be limited to 0.1 mg/kg because this concentration of methylmercury caused reduced reproduction in ducks (Eisler 1987a). Applying a factor of 5 for threshold effects and 2 for

whole fish yields a lower criterion for piscivores of 0.01 mg/kg. Lethal dietary concentrations of methylmercury range from 1 mg/kg for mink to 250 mg/kg for chickens (NRC 1980, Sheffy and St. Amant 1982, Wren et al. 1987, Eisler 1987a). We use 30 mg/kg, the approximate median LC₅₀, as an upper criterion for piscivores. Inorganic mercury is not relevant to this end point because the mercury in local fish is almost entirely methylmercury (R. R. Turner, ORNL Environmental Sciences Division, personal communication).

Nickel. The National Research Council (1980) set the maximum tolerable level of nickel at 50 mg/kg based on weight loss of cattle at 100 mg/kg in diet but no observed effects at 50 mg/kg. Chickens, the only tested bird, showed a statistically significant decrease in growth at 500 mg/kg in diet but not at 300 mg/kg (NRC 1980). Application of factors of 5 for variance in sensitivity and 2 for whole-fish concentration yields a lower chronic criterion for piscivores of 50 mg/kg. The oral LD₅₀ in rats is 350 mg/kg (NRC 1980). Conversion to dietary concentration yields an upper criterion of 4400 mg/kg, which is consistent with the sublethal dietary toxicity data.

Selenium. Dietary selenium effects are difficult to assess because the toxic levels are near the deficiency levels, uptake is highly variable among species, and uptake is highly dependent on the form of the selenium and how it is incorporated into food. Rats experience histological damage and reduced longevity in lifetime exposures to 3 mg/kg in naturally contaminated feed, but the same effects occurred at 0.75 mg/kg in spiked feed (Eisler 1985). Five mg/kg was a no-observed-effects level in feeding studies of mallards, and 6-9 mg/kg in feed reduced the hatchability of chicken eggs (Eisler 1985). Mortality and severe reproductive effects in birds occurred in an area with concentrations of 22-175 mg/kg in food items (Ohlendorf et al. 1986). Based on these data, the intermediate criterion is set at 1 mg/kg, which is just above recommended concentrations in diet to prevent selenium deficiency of 0.1-0.05 mg/kg (Eisler 1985). That threshold value is divided by 2 for the whole-fish conversion for a lower screening criterion for piscivores of 0.5 mg/kg in fish. The upper criterion is set at 100 mg/kg, the lethal dietary concentration in mallards (Eisler 1985).

Silver. The National Research Council (1980) set the maximum tolerable level for silver in animal food at 100 mg/kg based on studies of rats, chickens, and turkeys. Application of factors of 5 for variance in sensitivity and 2 for the whole-fish conversion yields a lower screening criterion for piscivores of 10 mg/kg.

Thallium. Thallium is highly toxic to mammals, and thallium salts have been used as rodenticides (Venugopal and Luckey 1978). It is also highly toxic to birds with an acute lethal threshold in diet of 12 mg/kg in bobwhite quail (EPA 1980a). The no-observed-effect level for thallium in the diet of rats is 5 mg/kg (EPA 1980a). Applying factors of 5 for variance in sensitivity and 2 for the whole-fish conversion yields a lower screening criterion for piscivores of 0.5 mg/kg. The upper criterion is set at the dietary LC₅₀ in rats of 30 mg/kg (EPA 1980a).

Zinc. The National Research Council (1980) set the maximum tolerable level for zinc in sheep feed at 300 mg/kg and in swine and poultry feed at 1000 mg/kg, but adverse effects on young Japanese quail fed laboratory diets occurred at 125 mg/kg (Hamilton et al. 1979). Using the Japanese quail datum as the intermediate criterion and applying a factor of 2 for the whole-fish conversion yield a lower screening criterion for piscivores of 60 mg/kg.

3.2.4 Organics in Fish

DDT and metabolites. DDT and its metabolites DDD and DDE are notorious for their effects on piscivorous birds. Birds experience reduced survival or reproduction at 3-0.15 mg/kg in diet (Lincer 1975, Anderson et al. 1975). Applying a factor of 5 for an effects threshold and 3 for the whole-fish conversion yields a lower criterion for piscivores of 0.01 mg/kg. The acute oral LD₅₀ for birds is approximately 1000 mg/kg (Matsumura 1985), which is equivalent to a dietary concentration in kingfishers of approximately 12,500 mg/kg, the upper criterion for piscivores. Fish themselves experience effects at 3-11 mg/kg body burden (EPA 1980c). Since 3 mg/kg is lethal to cutthroat trout fry, we apply the factors of 5 for an effects threshold and 3 for whole-fish-basis to obtain a lower criterion for protection of fish of 0.2 mg/kg.

Polychlorinated biphenyls (PCBs). PCBs are persistent, bioaccumulative, and highly toxic. Mink are the most sensitive species to PCBs, experiencing reproductive failure at 0.64 mg/kg in diet (Ringer 1983, Fuller and Hobson 1986). Birds experience reproductive and immunotoxic effects at 10-40 mg/kg in diet (Peakall 1986). Because these levels induce catastrophic reproductive effects, the International Joint Commission [IJC (1988)] recommends a concentration in fish of 0.1 mg/kg to protect piscivores. Using the mink effects level as the intermediate criterion and applying the factor of 5 for effects thresholds approximately yield the IJC criterion. Applying the factor of 3 for organics in whole fish yields a lower criterion for piscivores of 0.04 mg/kg. The acute dietary LC₅₀ in birds is 747-12,000 mg/kg (Peakall 1986). Using 1000 mg/kg and dividing by 3 for the whole-fish conversion yields an upper criterion of 300 mg/kg.

Other organics. All 104 of the other organic chemicals that were analyzed in fish tissues were not detectable. The detection limits ranged from 0.01 to 33 mg/kg with more than 10 fish sampled for all chemicals. Except for the pesticides, which are not generated or used in large amounts by DOE operations, there are very few dietary toxicity data or avian toxicity data of any sort for these chemicals.

The undetected chemicals that pose the greatest risk (absent toxicity data) are those with the highest detection limits. The three undetected chemicals with detection limits greater than 10 mg/kg are dinitrophenol, dinitrocresol, and benzidine. Dinitrophenols are intermediates in various industrial syntheses and are specific uncouplers of oxidative phosphorylation. The acute oral lethal dose to mammals ranges from 1 to 200 mg/kg with a median of approximately 20 mg/kg (EPA 1980f, NIOSH 1988). The threshold for dietary toxicity in male rats was 500 mg/kg. Dinitrocresols, which were formerly used as pesticides, have acute oral lethal doses in mammals and birds ranging from 8.3 to 85 mg/kg, with birds being a factor of 2 to 10 more sensitive than rodents (EPA 1980f, NIOSH 1988). The median LD₅₀ is 30 mg/kg. In one rat dietary test, 63 mg/kg of dinitrocresols was a no-observed-effects level, but 125 mg/kg caused lethaliies (EPA 1980f). We could find no appropriate data for noncarcinogenic effects of benzidine, but sublethal injury in rodent

dietary studies occurred at 100 and 430 mg/kg for chloro- and acetyl-substituted benzidine, respectively (EPA 1980e, NIOSH 1988). We use the diacetylbenzidine result because we judge that it is more likely to approximate benzidine toxicity than the dichlorobenzidine result. Applying a factor of 5 for variance in sensitivity and 3 for whole fish results in lower screening criteria of 30 mg/kg for benzidine and dinitrophenols and 4 mg/kg for dinitrocresols. Converting to a dietary basis yields upper screening criteria of 250 mg/kg for dinitrophenols and 375 mg/kg for dinitrocresols.

Several undetected organic chemicals had detection limits of 3.3 mg/kg in fish. Many of these are polycyclic aromatic hydrocarbons (PAHs). Effects other than carcinogenicity are poorly documented for this class of chemicals. Acute oral LD₅₀s for rats range from 50 to 9430 mg/kg with a median of approximately 1000 mg/kg (EPA 1980h, Eisler 1987b, NIOSH 1988). Converting to dietary concentration yields an upper screening criterion for all PAHs of approximately 12,500 mg/kg. There is not sufficient information to develop a lower screening criterion for exposure of piscivores to PAHs (EPA 1980g, EPA 1980h, Eisler 1987b, NIOSH 1988). However, the detection limit (3.3 mg/kg) is almost 100 times the lower criterion for PCBs, and the high biological activity of the 4-6 condensed ring PAHs suggests that they could have more than one one-hundredth of the toxicity to wildlife of PCBs. On that relatively weak basis, we estimate that dietary toxic effects might occur below the detection limit.

The next most common class of undetected chemicals with detection limits of 3.3 mg/kg is nonpesticide, nonphenolic chlorinated aromatic hydrocarbons. Because the oral toxicity of these chemicals is poorly characterized, the relatively well studied compound hexachlorobenzene (HCB) is used as a model compound for this group. The acute lethal dose is 1000 mg/kg or greater (EPA 1980i, EPA 1984b, NIOSH 1988), so the upper criterion for concentrations in fish is 12,500 mg/kg. HCB causes liver damage in Japanese quail at 5 mg/kg in diet (EPA 1980i) and causes immunosuppression in mink and ferrets (by different criteria) at 25 and 1 mg/kg in diet (Bleavins et al. 1983). Using the 1-mg/kg level as the intermediate criterion and applying a factor of 3 for whole-fish basis yield a lower screening criterion of 0.3 mg/kg for piscivores.

A third class of undetected chemicals with detection limits of 3.3 mg/kg is the chlorinated phenols. Median oral LD₅₀s are 500, 1000, and 100 mg/kg for monochloro, trichloro, and pentachloro phenols, respectively, and 1000 mg/kg for chlorinated cresols (EPA 1980o, EPA 1980p, EPA 1980q), yielding upper screening criteria of 6250, 12,500, 1250, and 12,500 mg/kg. Appropriate dietary or chronic oral toxicity data were found only for trichloro and pentachloro phenols. 2,4,5-Trichlorophenol caused mild histological damage at 3000 mg/kg in the diet of rats (EPA 1980p). This effect level is used as the intermediate criterion for all monochloro, dichloro, and trichloro phenols and the dichloro cresol because toxicity generally increases with increased chlorination. Pentachlorophenol caused decreased weight in parental rats and increased stillbirths at 30 mg/kg in the diet (EPA 1980q). Application of a factor of 10 for variance in sensitivity and 3 for whole fish yields a lower screening criterion for piscivores of 1 mg/kg for pentachlorophenol and 100 for the other chlorinated phenols.

Another class of undetected chemicals with detection limits of 3.3 mg/kg is phthalate esters. Oral LD₅₀ values for mammals range from 1000 to 34,000 mg/kg, with a median across esters and species of approximately 10,000 mg/kg (EPA 1980j, NIOSH 1988). Converting to whole-fish dietary basis yields an upper screening criterion for all phthalate esters and piscivores of 125,000 mg/kg. Threshold dietary effects levels in rats are 40,000 mg/kg for dimethyl phthalate; 50,000 mg/kg for diethyl phthalate; 2500 mg/kg for dibutyl phthalate; and 2000 mg/kg for bis-2-ethylhexyl phthalate (EPA 1980j, NIOSH 1988). Because we found no avian toxicity data, we apply a factor of 10 for variance in sensitivity and a factor of 3 for the whole-fish conversion to obtain lower screening criteria of 1000, 2000, 80, and 70 mg/kg for dimethyl, diethyl, dibutyl, and bis-2-ethylhexyl phthalate, respectively. Because we could not find appropriate data for dioctyl phthalate or butyl benzyl phthalate, we assigned them the same lower criterion as the ethylhexyl phthalate, 70 mg/kg.

Mononitrophenols also are undetected at detection limits of 3.3 mg/kg. Oral LD₅₀s for mononitrophenols range from 350 to 2800 mg/kg with a median of approximately 1000 mg/kg (EPA 1980f, NIOSH 1988). Converting

to dietary basis yields an upper screening criterion for piscivores of 12,500 mg/kg for mononitrophenols. We could find no dietary toxicity data or chronic oral dosing data for mononitrophenols. We assume that the relative chronic toxicity of nitrophenols is equal to their relative acute toxicities. Since dinitrophenols are three times as acutely toxic as mononitrophenols, the proportional lower screening criterion for mononitrophenols is 240 mg/kg.

Nitrobenzene is acutely lethal to mammals at a dose of approximately 700 mg/kg (EPA 1980k), which gives an upper dietary criterion of 8750 mg/kg. It causes degeneration of guinea pig organs at 50 mg/kg in diet (EPA 1980k). Applying a factor of 10 for variance in sensitivity and 3 for the whole-fish conversion yields a lower screening criterion for piscivores of 2 mg/kg.

Dinitrotoluenes (DNT) are primarily products of munitions industries. The median oral LD₅₀ for rodents is approximately 1000 mg/kg (Etnier 1986), which gives a dietary upper criterion of 12,500 mg/kg. A threshold dietary concentration for effects in rats is 1.5 mg/kg/day for 2,4-DNT, and the 2,6 isomer has approximately equal chronic toxicity (Etnier 1986). Applying a factor of 10 for variance in sensitivity and 3 for whole fish yields 0.05 mg/kg for DNT.

N-nitroso dimethyl, di-n-isopropyl, and diphenyl amines have LD₅₀s in rats of 40, 480, and 3000 mg/kg (EPA 1980l), which yield upper criteria of 500, 6000, and 37,500 mg/kg. Dietary effects of nitrosamines other than carcinogenicity are not sufficiently well documented to allow estimation of intermediate and lower criteria.

LD₅₀s for isophorone range from 1870 to 2370 mg/kg (EPA 1980m, NIOSH 1988). Using a median of 2000 mg/kg yields a whole-fish dietary upper criterion of 25,000 mg/kg. Isophorone reduced the growth of rats at 3000 mg/kg (EPA 1980m). Applying a factor of 10 for variance in sensitivity and 3 for whole fish yields a lower screening criterion for piscivores of 100 mg/kg.

LD₅₀s for phenol range from 100 to 600 mg/kg (EPA 1980n, NIOSH 1988). Using a median of 500 mg/kg yields a whole-fish dietary upper criterion of 6250 mg/kg. Phenol reduced the growth of rats consuming 55 mg per day in drinking water (EPA 1980n). Consumption of 20 g of food daily by a

200-g rat corresponds to an equivalent dietary concentration of 2750 mg/kg. Applying a factor of 10 for variance in sensitivity and 3 for whole fish yields a lower screening criterion for piscivores of 90 mg/kg. The phenol criteria are also used for methyl phenols.

All other organic chemicals were undetected, and the detection limits were 0.5 mg/kg or less. These chemicals were either not associated with DOE operations (e.g., toxaphene), are unlikely to cause toxic effects at the detection limits (e.g., toxaphene), or are unlikely to persist in off-site surface waters at significant concentrations (e.g., chlorinated solvents).

3.2.5 Radionuclides

Effects of radionuclides on nonhuman biota are not analyzed in this assessment for three reasons. First, previous studies of radionuclide exposure and effects in White Oak Lake found no evidence of effects or of exposures sufficient to cause effects in controlled exposures (Blaylock and Trabalka 1978), and concentrations of radionuclides are much lower off-site than in White Oak Creek (see Hoffman et al. 1990). Second, the mode of action of radionuclides is the same in nonhuman organisms as in humans so the ranking of radionuclides produced by the human health assessment, which includes bioaccumulation by fish and ingestion of fish by humans, would be applicable to ecological effects. Third, a screening assessment of radionuclide effects on nonhuman populations would have no consequences because an extensive off-site radionuclide monitoring program will be conducted for human health assessment regardless of potential ecological effects. The results of those studies, including body burden data for fish, birds, and mammals, will be analyzed for evidence of ecological risks in future assessments.

3.3 AMBIENT CONCENTRATIONS

Data concerning chemical concentrations in water, sediment, and fish flesh were compiled from various sources including surveys conducted by the Tennessee Valley Authority, Oak Ridge National Laboratory, and individual investigators, plus water treatment plant records. The specific data sources and the procedures for compiling the data are

described by Hoffman et al. (1990). Maxima consist of the highest detected concentration or limit of detection for a medium and reach. Mean concentrations are means of both detected concentrations and the limits of detection when concentrations could not be determined. When means included limits of detection they are reported as "<x."

3.4 CALCULATIONS

Results are obtained by dividing the concentrations in water, sediment, or fish tissues by the criteria to obtain quotients. Quotients greater than 1 indicate that the criterion was exceeded.

4. RESULTS

The mean and maximum concentrations in water, sediment, and fish flesh, and the results of comparisons to toxicological screening criteria are presented in Appendix A, arranged by medium. The results are summarized in Table 2 and are discussed in this section. However, there are some generic observations. (1) The concentrations of metals in sediment are largely irrelevant because they are total concentrations in dry sediment. For example, a concentration of >10% aluminum clearly includes phases which are not available to organisms, including strongly sorbed aluminum and mineral aluminum. Except for mercury, there is no acceptable means to estimate available metal concentrations. All of the maximum metal concentrations in sediments are above the lower screening criteria, all but antimony in MHR are above the chronic NWQC, and most exceed the upper criterion. All that we can conclude concerning metals other than mercury in sediments is that effects in benthic organisms cannot be excluded. Therefore, individual metals in sediments other than mercury are not discussed. (2) Although both mean and maximum concentrations of chemicals are included in the analyses, mean water concentrations are not discussed because nearly all are "less-than" values. (3) The maximum concentrations in water of all metals are above the lower screening criteria. Therefore, the discussions of metals in water will only address the cases in which the upper or intermediate screening criteria (i.e., acute or chronic NWQC or equivalent) were exceeded. (4) Although the problem is not as great as for sediment, the appropriateness of the aqueous concentrations is uncertain because the forms of the chemicals in water and the methods of analysis are not specified in the data base. Aquatic toxicity data are obtained from relatively pure laboratory waters, so the concentrations are most relevant to ambient measurements of dissolved and disassociated chemicals. However, the factor-of-6 difference between maximum iron and maximum dissolved iron in WBR suggests that the reported concentrations may include considerable particle-associated material. Even well-filtered samples contain chemicals that are associated with dissolved humic material and have variable speciation. (5) The factor-of-100 conservatism

Table 2. Summary of results: Media in which maximum values or limits of detection exceeded criteria, media for which critical reaches were measured, and necessary and desired sensitivity of chemical analyses

^aY indicates that the intermediate criterion for a medium is exceeded; y indicates that the lower criterion but not the intermediate criterion was exceeded; N indicates that no criteria were exceeded; ? indicates no toxicity data, bioaccumulation data, or K_{ow} data; and a blank indicates that the compound was not measured in the medium in any reach. Sediment maxima include all depths.

^bY indicates that the compound was measured in water or sediment in WOCC, PCE, and PCC, or in fish in WOCC and PCE. N indicates that not all of these critical reaches were measured.

^cThe necessary levels of sensitivity are the intermediate criteria and the desired levels of sensitivity are the lower criteria. A ? indicates no toxicity data, n.a. indicates chemicals with no significant dietary toxicity, and a blank indicates that the compound was not measured in that medium.

^dThe codes for criteria exceeded and reaches measured are based on total analyses, not the indicated chemical species.

of the lower criteria for water and sediments relative to the intermediate criteria (chronic NWQC) had little effect on the results. Very few chemical concentrations in water or sediments exceeded the lower criterion without also exceeding the intermediate criterion (Table 2). (6) In the following discussion the intermediate criteria for concentrations in water are referred to as "chronic NWQC" or "estimated chronic NWQC" and the upper criteria for concentrations in water are referred to as "acute NWQC" or "estimated acute NWQC" to emphasize the relationship of the reported concentrations to standard benchmarks. However, the reader should bear in mind that these results include water concentrations from nonstandard sampling and analysis methods and water concentrations estimated from sediment or fish tissue concentrations. Therefore, violations of standards are not implied by exceedances of these criteria.

4.1 RESULTS FOR METALS AND TOXIC INORGANIC CHEMICALS

Aluminum. Maximum concentrations of aluminum in WOCC and PCE water are above the upper criterion (proposed acute NWQC), and in WBR they are above the intermediate criterion (proposed chronic NWQC). Aluminum has not been measured in water in other reaches or in fish flesh in any reach.

Antimony. The detection limits for antimony in fish tissues are above the lower screening criterion for piscivores but below the intermediate criterion (the level that caused liver damage).

Arsenic. The maximum concentration of arsenic in WOCC water is above the acute NWQC, and in MHR it is above the chronic NWQC. Other analyzed reaches (PCE and PCC) have much lower maximum aqueous concentrations. However, analysis of fish tissues suggests that the fish in PCE and PCC have been exposed to potentially toxic concentrations of arsenic. These conclusions are based on the assumption that the arsenic is pentavalent. If it is trivalent, MHR and WOCC maximum water concentrations still exceed chronic NWQC, and the maximally contaminated fish in PCE were still apparently exposed to arsenic concentrations exceeding the chronic NWQC. Arsenic does not appear to pose a risk to piscivorous wildlife.

Boron. The maximum concentration of boron in PCE water exceeded the estimated chronic NWQC. It was not measured in water in other reaches or in fish tissues.

Calcium. The maximum aqueous calcium concentration in PCE, but not WBR, exceeded the estimated chronic NWQC. It was not measured in water in other reaches, and calcium concentrations are not pertinent to other media.

Cadmium. The maximum aqueous concentration of cadmium in PCE exceeded the acute NWQC. The chronic NWQC was exceeded by the maximum concentration in PCC, but not WOCC or PC. Detection limits exceeded cadmium criteria in MHR and WOCC. Fish tissue concentrations of cadmium suggest exposures that are considerably lower than the maximum measured aqueous concentrations in PCE and PCC and lower than chronic NWQC. Cadmium does not appear to pose a risk to off-site piscivorous wildlife. Cadmium appears to be slightly enriched in WOCC sediments relative to other reaches.

Chromium. The maximum concentration of chromium in MHR, WOCC, PCE, and PCC waters exceeded the acute NWQC, assuming that the chromium is hexavalent. All concentrations are below criteria for trivalent chromium. The maximum aqueous concentration in PC was below both criteria for both forms. Fish tissue concentrations of chromium suggest exposures that are considerably lower than the maximum measured aqueous concentrations in MHR, WOCC, PCE and PCC, and lower than chronic NWQC for both forms. However, the bioaccumulation factor for chromium is not well defined. Chromium does not appear to pose a risk to piscivorous wildlife. Chromium concentrations were elevated in WOCC and PCE relative to other reaches.

Cobalt. The detection limit for cobalt in PCE water exceeded the chronic NWQC, but the concentration in WOCC was below the chronic NWQC. Cobalt was not analyzed in sediment or fish flesh.

Copper. The maximum aqueous concentration of copper in MHR, WOCC, PCE, and PCC exceeded the acute NWQC. The chronic NWQC was exceeded in PC. The maximum concentration in WBR was below both criteria. Fish tissue concentrations of copper suggest exposures that are considerably lower than the maximum measured aqueous concentrations in MHR, WOCC, PCE and PCC, but still higher than the chronic NWQC in WOCC and PCE. Sediment

maximum and surface maximum (the highest concentration in a surface sample) concentrations of copper appear to be elevated in PCE.

Cyanide. The maximum aqueous concentration of cyanide in WOCC, PCE, PCC, and PC exceeded the chronic NWQC. Cyanide was not measured in any of the negative reference reaches or in fish tissues.

Iron. The maximum aqueous concentration of iron in WOCC, PCE, and WBR exceeded the chronic NWQC. The maximum iron concentration in MHR was less than one-tenth of that in WOCC and PCE, suggesting enrichment by sources on these creeks. Iron was not measured in any of the negative reference reaches or (for obvious reasons) in fish tissues.

Lead. The maximum concentration of lead in PCE water exceeded the acute NWQC. The chronic NWQC was exceeded in WOCC, PCC, and PC. The detection limit for lead in MHR was above the chronic NWQC, and lead was not measured in any negative reference reach. Concentrations in fish tissues suggest exposures much lower than the maximum measured aqueous concentrations, but the maximum concentration in MHR fish suggests an exposure concentration that exceeded the chronic NWQC. Except for the maximum concentration in PCE water, lead concentrations are similar among reaches for each medium.

Mercury. The maximum concentration of mercury in MHR water exceeded the acute NWQC. The intermediate criterion (estimated chronic NWQC) was exceeded in WOCC, PCE, PCC, and PC. Fish tissue concentrations suggest much lower exposure concentrations than the measured maximum water concentrations, but maximum tissue concentrations in PC, PCE, and PCC suggest exposure concentrations exceeding the intermediate criterion. The maximum tissue concentration in PCE exceeded the tissue concentration found in fathead minnows displaying toxic effects of chronic exposures to inorganic mercury (Snarski and Olson 1982). Pore-water concentrations estimated by applying the site-specific distribution coefficient to the maximum surface sediment concentrations exceed the intermediate criterion in WOCC, PCE, PCC, and WBR. Pore-water concentrations estimated from the maximum surface sediment concentrations in MHR and NR exceeded the lower screening criterion. Pore-water concentrations estimated from maximal and mean sediment concentrations over the sampled sediment columns exceed the intermediate criterion for all reaches except for the means in MHR and NR,

which exceed the lower screening criterion. Concentrations in MHR and NR sediments are less than one-tenth of the corresponding concentrations in other reaches. Mean mercury concentrations in fish are above the lower screening criterion for piscivorous wildlife in all reaches. Even without the correction for whole-fish concentrations, they exceed the concentration that reduces avian reproduction in PC, PCE, PCC, EF, and WOL. The maximum concentrations in fish from PCE and PCC exceed the dietary lethal concentration for mink.

Nickel. The maximum concentration of nickel in PCE water exceeded the acute NWQC. Neither NWQC was exceeded in other reaches.

Phosphorus. The maximum concentration of phosphorus in PCE water exceeded the acute WQC for elemental phosphorus. It is highly likely that the reported phosphorus appeared in other forms, which are much less toxic. Phosphorus was not measured in other reaches or media.

Phosphate. The maximum aqueous concentration of phosphate in PCE far exceeded the concentration of 25 µg/L that is sufficient to cause nuisance algal blooms.

Potassium. The maximum concentration of potassium in PCE water exceeded the estimated chronic NWQC. It was not measured in other reaches.

Selenium. The detection limit for selenium in PCE water exceeded the chronic NWQC. The maximum concentration in MHR was slightly below the chronic NWQC. Concentrations in fish tissues imply higher exposures (based on bioaccumulation factors) than the reported water concentrations, suggesting possible food-chain accumulation. Mean tissue concentrations in MHR, WOCC, PCE, PCC, and EF imply exposure concentrations in excess of chronic NWQC, and maximum tissue concentrations in PCC imply exposure in excess of acute NWQC. The maximum fish tissue concentrations in PCC and the maximum concentration in MHR exceed the intermediate criterion for piscivorous wildlife. Selenium concentrations in water appear to be elevated in WOCC, PCE, and PCC, relative to MHR and WBR.

Silver. The maximum concentration of silver in PCE water and the detection limit in WOCC exceeded the estimated acute NWQC. Concentrations in fish tissues imply higher exposures than the water concentrations, suggesting possible foodchain accumulation. Mean tissue concentrations

in MHR, WOCC, and PCE imply exposure concentrations in excess of the chronic NWQC, and maximum tissue concentrations in MHR imply exposure in excess of the acute NWQC. Sediment concentrations of silver appear to be elevated in WOCC and PCE.

Sodium. The maximum aqueous concentration of sodium in PCE exceeded the estimated chronic NWQC.

Thallium. The mean concentration of thallium in fish flesh from MHR exceeded the lower criterion for piscivores, and the limit of detection in other reaches exceeded that criterion.

Uranium. The maximum aqueous concentration of uranium in PCE exceeded the estimated chronic NWQC, and uranium concentrations are elevated in PCE relative to other reaches.

Vanadium. The detection limit for vanadium in PCE exceeded the estimated chronic NWQC.

Zinc. The maximum concentrations of zinc in WOCC, PCE, and PCC exceeded the acute NWQC. Maximum concentrations in MHR, WBR, and PC were below both criteria. The concentrations of zinc in fish tissues imply exposure concentrations that are somewhat lower than the maximum water concentrations, are quite consistent among reaches, and are below the chronic NWQC.

4.2 RESULTS FOR ORGANIC CHEMICALS

Acrolein. The detection limit for acrolein in sediment corresponds to an estimated pore-water concentration that exceeds the acute NWQC.

Benzidine. The detection limit for benzidine in sediment corresponds to an estimated pore-water concentration that exceeds the acute NWQC.

Chlordane. The limit of detection for chlordane in sediment corresponds to an estimated pore-water concentration that exceeds the acute NWQC.

Chlorinated aromatics. Several chlorinated aromatic compounds have detection limits in fish flesh that exceed the intermediate criterion for effects of the class on piscivorous wildlife.

DDT. *p,p'*DDT was detected in fish tissues in MHR and WOCC at maximum concentrations that imply aqueous exposures above the intermediate

criterion (chronic NWQC) and mean concentrations above the lower criterion. The body burdens are below concentrations that have been associated with overt toxic effects on fish (EPA 1980c), but in MHR they approximately equal the lower criterion. Because DDT is no longer legally used and because of its hydrophobic properties and its tendency to biomagnify, it is likely that these concentrations result from feeding on benthic organisms rather than bioconcentration. The maximum concentration in fish flesh from MHR exceeds the intermediate criterion for piscivores, and mean concentrations in MHR and WOCC barely exceed the lower criterion for piscivores.

Dieldrin. The limit of detection for dieldrin in sediment corresponds to an estimated pore-water concentration that is above the chronic NWQC.

Dinitrotoluene. The detection limits for the 2,4 and 2,6 isomers of dinitrotoluene in sediment correspond to estimated pore-water concentrations that exceed the chronic NWQC.

Endosulfan isomers. The limit of detection for endosulfan in sediment corresponds to an estimated pore-water concentration that exceeds the acute NWQC.

Endrin. The limit of detection for endrin in sediment corresponds to an estimated pore-water concentration that exceeds the acute NWQC. The detection limit in fish flesh corresponds to an estimated fish exposure concentration in excess of the chronic NWQC.

Heptachlor. The limit of detection for heptachlor in sediment corresponds to an estimated pore-water concentration that exceeds the chronic NWQC.

Hexachlorocyclopentadiene. The limit of detection for hexachlorocyclopentadiene in PCE water was above the acute NWQC. The detection limits in fish flesh correspond to an estimated fish exposure concentration in excess of the chronic NWQC.

Nitrophenol. The detection limit for 4-nitrophenol in sediment corresponds to an estimated pore-water concentration that exceeds the chronic NWQC.

Nitrosamines. The detection limits for nitrosamines in sediment correspond to estimated pore-water concentrations that exceed either the

acute NWQC or the intermediate criterion, depending on the particular nitrosamine.

Pentachlorophenol. The maximum concentration of pentachlorophenol in PCE water exceeded the acute NWQC.

Phenols. The maximum, surface maximum, and mean concentrations of phenols in MHR sediments correspond to estimated pore-water concentrations in excess of the acute NWQC for phenol.

Phthalate esters. The limits of detection for phthalate esters in PCE water were above the chronic NWQC. The limits of detection in sediments correspond to estimated pore-water concentrations that exceed acute NWQC. Phthalate esters that were detected appear to be elevated in sediments from PCE.

Polychlorinated biphenyls (PCBs). The detection limit for PCBs in WOCC and PCE waters exceeded the chronic NWQC. In sediment, only PCBs 1254 and 1260 exceeded detection limits, and the estimated pore-water concentrations for both exceeded the intermediate criterion (chronic NWQC) in the WOCC. In other reaches, sediment concentrations were below detection limits and above lower and intermediate criteria. Aqueous exposure concentrations for fish estimated from the maximum fish tissue concentrations suggest that fish exposures to PCBs have been below the lower criterion in MHR, WOCC, PCE, PCC, WBR, TR, and WOL. Maximum total PCB, PCB 1254, and PCB 1260 concentrations in fish exceeded the intermediate and lower screening criteria for piscivores in all measured reaches, and mean fish concentrations exceed both criteria in all but MHR and TR, where only the lower criterion was exceeded.

4.3 SUMMARY OF RESULTS

The reported maximum aqueous concentrations of aluminum, arsenic, boron, calcium, cadmium, chromium, copper, cyanide, lead, lithium, mercury, nickel, silver, sodium, uranium, and zinc exceeded acute or chronic NWQC or estimated equivalent values in off-site reaches that are influenced by DOE Oak Ridge facilities (WOCC, PCE, PCC). In addition, the maximum aqueous concentration of pentachlorophenol exceeded the acute NWQC, and PCB concentrations exceeded the chronic NWQC in WOCC and PCE. Application of bioaccumulation factors to concentrations of arsenic,

cadmium, copper, lead, selenium, and silver in fish tissues appears to confirm that exposures to high aqueous concentrations have occurred. However, concentrations of chromium, mercury, nickel, zinc, and PCBs in fish tissues suggest exposure concentrations that are lower than NWQC. These results suggest that toxic effects have occurred in these waters. The magnitude and extent of these effects cannot be estimated because the form of the chemicals and their temporal and spatial distributions are undefined. Because the measurements may include biologically unavailable forms of the chemicals, the effects may be much smaller than these results suggest.

As was discussed earlier, the available sediment concentrations for metals other than mercury are uninterpretable. Estimated pore-water concentrations of mercury exceed chronic NWQC, suggesting that benthic organisms are affected. Intermediate criteria were also exceeded by the maximum estimated pore-water concentrations of Bis(2-ethylhexyl)phthalate in PCE and of phenanthrene in PCE and PCC. The detection limits for many organic chemicals would result in pore-water concentrations that greatly exceed NWQC.

Fish tissue concentrations of mercury are sufficient to cause toxic effects in piscivorous wildlife in all measured reaches including TR, but particularly in PCE and PCC. Selenium in fish from PCC and thallium in fish from MHR may be toxic to wildlife. DDT in the most contaminated fish from MHR and WOCC is sufficient to cause eggshell thinning in piscivorous birds. Mean PCB concentrations in fish are sufficient to cause reproductive failure in mink in all reaches but MHR and TR, and mean fish concentrations in those reaches are barely below the observed-effects level. These results indicate that piscivorous wildlife along the Clinch River are at risk.

Although this screening assessment was intended primarily to eliminate chemicals from further consideration, it has eliminated relatively few. Metals in general cannot be eliminated because of the inability to interpret sediment concentrations and the high concentrations of several metals in water, sediment, and fish flesh, discussed above. Most of the organic chemicals measured in water were undetected and below screening criteria. However, only chloroform, bromodichloromethane,

phenols, and total PCBs were measured in any reach other than PCE, and they were measured only in WOCC. Therefore, organics in water can not be eliminated. Most priority organics were measured in sediments from MHR, WOCC, PCE, PCC, and NR. Most were undetected, and some can be eliminated because the quotients in Tables A-3 through A-5 have negative exponents (i.e., the estimated pore-water concentration is below the lower criterion), but many are not eliminated. Most priority organics were measured in fish flesh from MHR, WOCC, and PCE, but not from reference reaches. Most were undetected, and many can be eliminated because the quotients in Tables A-6 and A-7 all have negative exponents, but it is not possible to determine whether concentrations are elevated or what the sources are because of the absence of reference values. Finally, the occurrence of several chemicals in multiple media at potentially toxic concentrations raises the issue of combined toxic effects that are greater than those induced by any single chemical. Given these results, it is advisable to deemphasize the measurement of sources of exposure relative to the measurement of biological indicators of exposure and effects.

These results are compared to the results of screening for human health effects in Hoffman et al. (1990). Some chemicals are high priority for ecological effects but not human effects including aluminum, copper, lead, and manganese. Others such as mercury are of high priority in more reaches for ecological effects than for human effects. Several other chemicals are high priority for health effects but not ecological effects.

5. DATA NEEDS FOR ECOLOGICAL RISK ASSESSMENT

Although the off-site risk assessment is logically retrospective (i.e., it is concerned with the ongoing effects of past releases), this screening assessment is based on predictive risk assessment methods (i.e., it uses data concerning potential sources of exposure to predict the effects). The actual ecological risk assessment will use an epidemiological approach, in which sources, exposure, and possible effects are measured, and the results are used to determine (1) whether effects are occurring, (2) whether the effects are caused by particular sources, (3) what the actual magnitude and extent of effects are, and (4) what the consequences of remedial alternatives might be.

5.1 DATA NEEDS FOR SOURCE CHARACTERIZATION

The screening assessment is primarily useful in characterizing the sources (contaminated water, sediment, soil, and foodchain species). All of the sources are incompletely characterized, and some are not characterized in ways that are useful for ecological risk assessment. Problems with the source characterization include the following:

- (1) Whole-sediment concentrations are not directly useful for assessing ecological effects, and, in the case of metals, they are not even indirectly useful. Measurement of chemical concentrations in sediment pore water (or elutriate if pore-water sampling is not feasible) rather than digests of whole dry sediment would be directly applicable to estimating exposure and effects in benthic organisms. If pore water or elutriates cannot be analyzed in all samples, they must be analyzed in enough samples to establish site-specific distribution coefficients.
- (2) The form and species of chemicals in water are not characterized. At least, the metals that have separate NWQC for each species (chromium and arsenic) should be analyzed by species. Also, water analyses should be done for dissolved forms.
- (3) Fish body burdens as a source of exposure for piscivorous wildlife are not appropriately characterized. The analyses of "edible portions" for human consumption do not represent the exposure of piscivorous wildlife that consume the whole fish. Some whole-fish analyses should be performed to establish the ratios of whole fish

to edible portion concentrations. (4) Much of the data is not useful because it is reported as "undetected" or "<X." Although some of these results represent chemicals that were genuinely undetected, others represent cases in which the chemical was detected but could not be quantified accurately. Risk assessments would be greatly improved if the results of such analyses were reported as the best estimate of the concentration plus an estimate of observation error (Porter et al. 1988). (5) The analyses are quite inconsistent among reaches. The comparisons among reaches that are needed to identify the sources of contamination are not possible unless the chemicals of concern are all analyzed in all media and reaches. Also, the sampling intensity should be the same in all reaches or should be sufficient to completely characterize the reaches.

Ideally, the characterization of off-site sources of exposure would begin with a list of chemicals that have been emitted from point sources or deposited in leaky waste sites and would then proceed to reduce that list by analysis of ambient media. However, neither emissions nor wastes have been sufficiently characterized, so the ambient monitoring must address the entire priority pollutant list plus radionuclides. As discussed above, the priority pollutants have been irregularly monitored and measurement methods have not always been appropriate, so it is difficult to identify chemicals that can be shown to pose no environmental risk. In addition, the toxicity of many chemicals has not been sufficiently characterized. However, examination of Table 2 reveals some chemicals in some media that do not need to be analyzed for assessment of ecological risks. If a chemical was measured in the reaches that are most influenced by DOE emissions and did not exceed criteria, it can be eliminated. The critical reaches are judged to be WOCC, PCE, and PCC. Hence, chemicals can be eliminated that, for a particular medium, have an N(o) for criteria exceedance and a Y(es) for measurements in critical reaches. For example, 4-bromophenyl phenyl ether does not exceed criteria in sediments and was measured in sediments from the critical reaches, so new measurements in sediment are not needed.

5.2 DATA NEEDS TO CHARACTERIZE EXPOSURE

Exposure can be characterized by analysis of measured body burdens and biomarkers that are diagnostic of exposure to particular contaminants or classes of contaminants. Body burdens in fish can be used to estimate the degree of exposure of fish to chemicals. The analyses should be whole-body or, if target organs have been identified, organ-specific, not "edible portions." Also, as with the analyses of sources, the sampling and analysis need to be more consistent among reaches. Biomarkers of exposure may be analyzed in the off-site biological samples, but they have not been selected. Given the evidence that piscivorous wildlife are at risk, it would be desirable to also monitor them. This is difficult in general because they are not abundant. However, a great blue heron rookery near the ORGDP could be monitored for contamination of food and eggshells, and young birds that fall from the nests could be examined for signs of effects and chemically analyzed to estimate exposure.

5.3 DATA NEEDS TO CHARACTERIZE EFFECTS

Effects on assessment end points (e.g., reduction in fish populations and reduction in the reproductive output of bald eagles) can be estimated in three ways. The most direct and potentially the most reliable way is to measure the end point responses in the receiving environment (e.g., measure the abundance of fish populations), but these effects are difficult to measure because the natural variability in population-level characteristics tends to mask small effects and may even mask large effects. However, it is important to measure the end point responses because the measurements may reveal apparent effects, and, even if they do not, they can provide an upper bound on the magnitude of effects that could be occurring. The available information on the biota of the off-site receiving communities is sufficient to indicate that DOE's emissions have not had a catastrophic effect on those communities. However, that information is not sufficient to determine whether populations have been affected. The measures of effects on fish have not yet been chosen.

A less direct way of estimating effects on assessment end points is to infer those effects from measurements of effects on organismal and

suborganismal characteristics. Two sorts of indirect measures are useful. First, measures of toxic effects are needed that can be used to estimate the magnitude of effects on the end points. For example, measurements of growth rates of individual fish can contribute to the estimation of population productivity. Second, it is desirable to have diagnostic measures of effects to help identify the causes of observed overt effects. Indirect measures of effects will be obtained from fish and may be obtained from piscivorous wildlife.

6. APPROACHES FOR ECOLOGICAL RISK ASSESSMENT

Two approaches for ecological risk assessment will be employed for the later phases of the off-site assessment project. First, data concerning concentrations of chemicals in water, sediments, and fish will be used to refine the lists of chemicals of concern. The refinement will result from use of new data and from refinement of the assumptions used to develop the criteria. For those organisms such as piscivorous wildlife that are not currently included in the biological monitoring, this is the only basis for assessment.

Because indicators of effects will be measured in fish, it will be possible to employ an epidemiological approach to assess effects on fish. This approach will use the indicators of effects and supporting data to answer the following four questions:

(1) Are real toxicological effects occurring? That is, is there evidence that the fish exposed to DOE emissions are injured? Answering this question will require establishing that there are specific injuries or signs of debility in the fish that are not normal for the species and habitat type, or that species of fish that should occur in the habitat are not present or are present in very low numbers relative to their expected abundance. Thus, habitat analysis and establishing the "normal" state of health of the fish would be required.

(2) What is the cause of the effects? Establishing that the effects (if any) are caused by DOE effluents will require satisfying Koch's postulates, as modified for toxic effects (Suter, in press). First, a regular association must be established between the effects and the source. This requires that a particular effects syndrome be identified and that the syndrome be found regularly in fish exposed to the DOE effluents and not in reference reaches (i.e., those that are clean or at least are exposed to effluents that are not similar to the DOE effluents). Second, the fish that display the effects must also display evidence of exposure (i.e., body burdens or biomarkers of exposure). Third, the pollutants must be shown to induce effects in controlled exposures (i.e., toxicity tests). To establish the toxicity of existing water and sediment, the toxicity of these whole media can be tested in the

laboratory. If toxicity is demonstrated, then it is desirable to determine which components are responsible for the toxicity. This can be done by comparing the concentrations of chemicals in the media to existing toxicity data or by tests of spiked site water or sediment. Fourth, to establish the relevance of the controlled exposures to the observed effects in the field, it should be shown that the same effects occurred at similar levels of exposure in the laboratory and field. If there is good evidence that fish are being affected but this analysis indicates that the effects are not attributable to direct toxic effects, other causes should be considered. In particular, toxic effects on foodchain organisms should be investigated.

(3) What are the magnitude and extent of the effects? This question might be answered in a variety of ways depending on the nature of the effects and the data supporting the attribution of effects to pollution. If end point effects are measured in the field, then the problem is to describe the distribution of those effects in space and relative to concentrations of individual pollutants or indices of multiple pollutant exposure. If effects are shown to occur at the organismal or suborganismal levels, then the relationship between the lower-level effects and the population-level end points must be established before the distribution of effects can be described. It may be desirable to use results of water or sediment toxicity tests, rather than measurements of field-collected organisms, to establish the distribution of effects.

(4) What are the ultimate consequences of potential remedial actions? Ultimately, if significant ecological effects are shown to be occurring, it will be necessary to consider the consequences of alternative remedial actions on the magnitude and extent of effects. This will be done by using the models developed to describe the current effects (i.e., to answer question 3) to extrapolate into the future.

^a"<" indicates that the chemical was not detected and the reported concentration is the highest reported limit of detection; and "A" indicates that the value reported is the mean of two or more determinations.

a"<" indicates that the chemical was not detected and the reported concentration is the highest reported limit of detection; and "A" indicates that the value reported is the mean of two or more determinations.
